**Abstract:** This study encompasses the investigative effect of rooting media in addition to Indole Butyric Acid hormone on root development of stem cuttings of *Chromolaena odorata*. Stem cuttings of *C. odorata* treated with equal quantities of IBA hormone (0.7\%) were grown in 1kgs of vermiculate, perlite, planting soil, sand, and equal mixture of all media. The set up were treated equally with water and organic manure. Control set up was made with a mixture of different rooting media without IBA. Data on shoot development were noted for 6weeks and root length was measured on the day of harvest. The parameters measured were analysed statistically using ANOVA, and it was found out that root and shoot lengths were significant at p>0.05 in the entire rooting media and the highest percentage development (49 and 51\%) respectively for root and stem respectively, was observed in the rooting media that has equal measure of each constituent (i.e. the mixed constituents). Germination rate among the media were 100, 70, 60, 50 and 40\% for mixed, sand, planting soil and vermiculate, perlite and control respectively. Different sections of mature stem tested with IBA hormone were not significant in their root and stem development, although basal cutting stems tend to mature faster than epical. This therefore means that propagating *C. odorata* by stem cutting can be optimally achieved through mixture of 0.7\% of IBA in a collection of different rooting media.

**Keywords:** *Chromolaena odorata*; Indole butyric acid; Root formation; Rooting media.

**Introduction**

*Chromolaena odorata* (L) King and Robinson is referred to as Asteracaea and is commonly known as siam weed. The plant is an invasive shrub of the neotropical origin, but have been introduced to Africa and Asia in addition to other parts of the world (Singh et al. 2009). *C. odorata* is a fast growing oppressive competitor occupying different kinds of arable land by forming dense strands that tends to prevent the growth of other flora. Therefore it affects plantation and other organisms in the ecosystem, by its suppressive effects to young plants as it is a growth inhibitor and has allelopathic capabilities. Review of literature revealed a lot of pharmacological and medicinal effects of extracts of *C. odorata*, which informed the traditional uses of the plant especially in Asia to cure various disease ailments (Che Man 2010). These properties as exhibited by *C. odorata* are as a result of the phytochemical composition of the plant.

The medicinal properties of plants lies in their phytochemicals components like alkaloids, flavonoids, tannins in addition to other phenolics that co-opt as to producing definite physiological functions to the body of man and animals (Taiwo et al. 2000; Che Man 2010). However, analysis of extracts of *C. odorata* were found to be rich in flavonoid and flavonones, triterpene, terpenic compounds, chalcone, steroids as well as peroxidise isoenzymes (Anup et al. 201). It is also rich in carbohydrates, high content of total proteins in addition to high percentage of nitrogen. All these contribute to the high phytochemical properties of the plant. *C. odorata* is therefore grown as a medicinal plant for the treatment of skin wounds especially in Indonesia (Metwally and Ekejuba 1981; Phan et al. 1996). In Nigeria for example, extracts from the leaf of *C. odorata* is used for the treatment of fresh wound, this is because of its antispasmodic, antiprotozoal, antibacterial, antihypertensive, analgesic, anthelmintic as well as anti-trypanosomal activities as was reported by...
Taiwo et al. (2000), Phan et al. (1996), Akinmoladun et al. (2007) and Anup et al. (2011). *C. odorata* has also been implicated by its diuretic, hepatotropic and astringent properties (Weninger and Robenean 1988; Iwu 1993).

Traditionally, boiled fresh leaves of *C. odorata* have been used in so many countries for the treatment of various skin ailments. For example in Vietnam, decoction of the plant were used to treat leech bite, burns, wounds of the soft tissue, as well as other skin infections (Phan et al. 2001; Che Man 2010). The leaf poultice of the plant has also been traditionally used in the treatment of fresh cut or wounds as an aid to stop bleeding. In other instances, *C. odorata* were implicated in the treatment of sting from a pine of sea catfish, its root used as analgesic and antipyretic remedy and the extracts from the leave mixed with table salt could be used as gargle for the treatment of sore throat and flu (Che Man 2010). For some time now, *C. odorata* were just known for its medicinal properties but, recent studies has implicated the plants in biotechnology where it has been found used in phytoremediation of organic and inorganic contaminants (Singh et al. 2009, Tanhan 2011). *C. odorata* can be propagated either by seed or stem, this is one of the significant agronomic properties of the plant (Tanhan et al. 2007). However, it has been reported that germination of seeds from weeds are most likely affected by soil compositions especially in the field study therefore propagation by cutting is preferred (Adebayo et al. 2005; Agbo and Obi 2007). Moreover, stem cuttings propagation prolongs hybridization of genome as segregation through recombinant gene is avoided.

The success of rooting of stem cuttings has been attributed amongst other factors to the rooting medium as well as the presence of rooting hormone and its concentration (Al-Saqri and Alderson 1996; Hartmann et al. 1997). Influences of rooting media and hormone on rooting in different kinds of plant have been documented and its effects in structure propagations were elucidated (Akwatulira et al. 2011). These media combination used in the rooting of cuttings provide physical support as well as oxygen and water to the cuttings (Larsen and Guse 1997). However, IBA; an auxin containing product was reported to stimulate adventitious roots in apical cuttings of some plants (Araya et al. 2007). This was buttressed by the study by Rao et al. (2005) which reported that IBA was the leading plants hormone used to promote the formation of roots in Tomatoes. Hence with the quest for a systematic search for specific useful factors from medicinal plants like *C. odorata*, even though most plants cuttings can root without hormone, there is need for an improved method of propagation and growth for such nutraceutical plants. This will therefore form a rational approach towards drug and nutritional research. The aim of this study was to evaluate the effect of IBA hormone and rooting media for optimal rooting of propagated *C. odorata* stem cuttings.

**Materials and methods**

Mature stems of *C. odorata* plants was collected from the greenhouse at the University of South Africa in Pretoria (25°46’1”S, 28°12’2”E) and 1439m above sea level. The mature stems were made into cuttings of 10cm containing at least a node and a leaf bud. The experiment took place in polyvinyl chloride (PVC) pots with dimensions 30x25x30 at a garden at the University of South Africa. The pots contain 1kgs of different rooting medium that has been mixed with equal volume of organic manure collected at the animal farm of the University of Pretoria in Onderstepoort. Inside each pot was made holes designed to contain equal weight of IBA hormone (0.7%), for the plants. The set up was made in a complete randomized design containing a 3x4 factorial treatment model (Jeruto et al. 2008). The rooting media used here were vermiculate, planting soil, sand, perlite, planting soil and a mixture of equal volume of the four medium (w/w). About thirty six stem cuttings were used in each set of rooting media and IBA hormone concentration by volume percentage. Then sets of water treated cuttings were inserted into holes containing the IBA hormone in the rooting media and were replicated by three. Random allocation of cuttings to the rooting media using random digit from a table was employed as to eliminate bias (Johnson and Bhatcharyya 2006).
The effects of IBA on rooting of *C. odorata*

**Rooting media**

The rooting media was homogenized by hand, mixed with equal volume of organic manure and air dried on an impervious polythene sheet for 24 hours, there were pasteurized and fumigated, measured into the PVC pots with the hole containing about 0.7% of IBA hormone. This concentration was chosen because of its optimum performance from other unpublished trials.

**Propagation of the cuttings**

The 10.0 cm cuttings with lateral buds were about 360 collected at tale end of the afternoon when the weather was moist, and were kept in a bowl containing water (Agbo and Obi 2007). The bases were made squared by the use of sharp sickle in order to spread the rooting. For each of the cuttings, about half of it was dipped into the IBA hormone that has been made into hole in each of the pots as to soak the powder. Excess of it was shaken off the base of the cuttings and the hormone was manually made to concentrate at the base. The cutting was then inserted into the soil to about 6 cm, watered and maintained to about 70% humidity (Tanhan et al. 2007). Fungicides were sprayed onto the cuttings to control infections (Yeboah and Amoah 2009). The set up was allowed to grow for six weeks while monitoring in between days to remove any invading weeds. Data on shoot development was taken at interval of weeks and root length was measured on the day of harvest after weeks.

**Data collection**

Data collection which commenced on the first week after propagation continued till the sixth week and the parameters measured were survived cuttings, length of shootings/buds, and the root length, number and weight of the cuttings on the day of harvest.

**Data analysis**

The data collected was analysed using Microsoft excel to obtain the mean number and percentage of cuttings that were able to form developed root and sprouted shoots from the series of stem cuttings. The data was then imported into SPSS version 13.0 and was analysed using analysis of variance (ANOVA) and standard deviation for the length of shoot and roots. The significance effects were determined at 5% level of significance.

**Results**

Results of the present study are given in Figures 1 to 7 and Tables 1 & 2. *C. odorata* cuttings treated with concentration of 0.7% (w/w) IBA hormone propagated in different growth media recorded the highest mean number of cuttings that developed roots and sprouted shoots in the set up with equal mixtures of the four growth media with organic manure. While the stem cuttings propagated in the perlite and control recorded the least mean rooted (2 each) and sprouted shoots (4 and 3) as recorded in Table 1. Amazingly, perlite and vermiculate maintained almost equal numbers of shoot developed (4 and 3 respectively) like in the root (2 each). However, significant difference existed among the different media with reference to their mean rate of development and formation of root and shoot. The efficacy of IBA hormone to the development of root and shoots was noticed by the difference between the treated samples and the controls without the hormone. There was significance difference between the two samples.

Discussion

The rooting medium suplement that has mixtures of planting soil, perlite, sand and vermiculate at equal proportion enabled highest development of root and shoot in a cutting of C. odorata. This improved effect could be attributed to the fact that the combined nutrient supplement of the entire rooting media acted optimally with the IBA hormone concentration added which created the enabling soil condition for example, optimum aeration and moisture level (Kalyoncu and Ozer 2000; Akwatulira et al. 2011). Meanwhile dose application of IBA hormone was shown to be an aid to improved moisture content in the soil for an optimal rooting and shooting development of cuttings (Milletton et al. 1980; Leakey et al. 1982; Aminah et al. 2006; Akwatulira et al. 2011). However, most of these past studies maintained their IBA hormone concentration to about 0.7-0.8% of the rooting media used while this study based its IBA measurement on the weight of the cuttings. Moreover, the control sample of rooting medium supported low development of root and shoot than the auxin treated samples in the entire experiment. This could perhaps be because soil resistant to root penetration is dependent on amongst other factors on water content, structure and strength of soil as well as bulk densities though these were not measured in the rooting media (Amri et al. 2009). Soils do not posses the required aeration porosity for optimal gas exchange required for rooting of the cuttings resulting in poor rooting in the control. Poor rooting numbers in control could also be attributed to the feel of anoxia which is an effect of low oxygen in the soil (Hartmann et al. 2002). Low incidence of rooting was found in the control samples. Nonetheless, there are instances where optimum concentration of IBA in the soil has resulted in the failure of the development of roots by stem cuttings as was reported by Griffin and Shroeder (2004). That was an indication of the sensitivity of root formations to hormone formulations (Akwatulira et al. 2011). It has also been reported that rooting hormone to a certain instance could be inhibitory to the development of roots in the cutting especially during the initiation stage (Akwatulira et al. 2011). This then means that different rooting media accommodates different concentration of auxin for optimal growth of plants.
Conclusions

Mixture of various rooting media in the right proportion with 0.7% of IBA hormone has been proven to be effective in the root and shoot development of cuttings of Chromolaena odorata irrespective of the position of the cuttings. Although the individual medium did not have high incidences in most of the parameters measured, but there were able to support root and shoot development as well. Therefore, there is need for a study of IBA concentration effects on the media as to be able to determine if concentration was not the factor responsible for the low root and shoot development. This will promote mass production of C. odorata especially in areas that the plants does not occur naturally.
